Abstract—Graph algorithms have wide applicability to a variety of domains and are often used on massive datasets. Recent standardization efforts such as the GraphBLAS are designed to specify a set of key computational kernels that hardware and software developers can adhere to. Graphulo is a processing framework that enables GraphBLAS kernels in the Apache Accumulo database. In our previous work, we have demonstrated a core Graphulo operation that performs large scale multiplication operations of database tables called TableMult. In this article, we present results of scaling the Graphulo engine to larger problems and scalability when using greater number of resources. Specifically, we present the results of two experiments that demonstrate Graphulo scaling performance as linear with the number of available resources. The first experiment demonstrates cluster processing rates through Graphulo’s TableMult operator on two large graphs, scaled between \(2^{17}\) and \(2^{19}\) vertices. The second experiment uses TableMult to extract a random set of rows from a large graph (\(2^{19}\) nodes) to simulate a cued graph analytic. These benchmarking results are of relevance to Graphulo users who wish to apply Graphulo to their graph problems.

I. INTRODUCTION

Large scale graph analytics are of interest in a variety of domains. For example in an Intelligence, Surveillance and Reconnaissance (ISR) application, graph analytics may be used for entity matching or track analysis. For social media applications, graph analytics may be used to determine communities or patterns of interest. Recently, an effort known as the GraphBLAS [1], [3] (http://graphblas.org/) has sought to standardize a set of computational kernels and demonstrate their applicability to a wide variety of graph analytics [4]. The connection between graph processing and linear algebra is well-defined in [5], [6]. The GraphBLAS specification [6]–[8] currently consists of five core operations: sparse matrix multiplication, element-wise matrix multiplication, matrix addition, reference and dereference along with a small number of additional helper functions.

Given the vast majority of data is stored in databases such as Apache Accumulo, there is also interest in developing processing frameworks such as GraphX [9], Pregel [10], Gaffer [11] and Graphlab [12] optimized for graph operations on data in databases. A survey of popular graph database models is provided in [13]. It is natural that a processing framework designed for databases make use of the GraphBLAS kernels.

Graphulo [14] is a specialized graph processing framework built to work with Apache Accumulo that conforms to the GraphBLAS standard. Apache Accumulo is a NoSQL database infrastructure designed for high performance ingest and scans [15], [16]. As a general-purpose warehousing solution, Apache Accumulo has seen wide adoption in a variety of government and non-governmental settings.

As shown in Figure 1, Accumulo has a Key that is decomposable into a 5-tuple of row, column family, column qualifier, visibility and timestamp values. For simplicity, Graphulo provides directed graph structures using the row (source vertex), column qualifier (destination vertex) and the Value (the number of connections between the two vertices). The Visibility and Timestamp attributes are not investigated in this paper.

![Accumulo Key-Value Data Model](image)

Fig. 1. Accumulo Key-Value Data Model

One of Accumulo’s advantages over other data warehousing solutions is its **Iterator** framework, which allows for native in-database computation. This provides improved performance by exploiting data locality, avoiding unnecessary network transfers and moving the processing to the stored data. Additionally, by co-locating storage and computation, one can take full advantage of other aspects of Accumulo’s infrastructure such as write-ahead logging, fault-tolerant execution and parallel load balancing of data. As a first-order operator, iterators have full access to Accumulo’s data model allowing for highly flexible, server-side algorithm development capabilities.

In the remainder of this paper, we provide a brief high-level review of Graphulo in Section II, including a description of the Accumulo iterators used and the process for tracking the amount of work done in each experiment. Section III presents the main SpGEMM scaling experiment using Graphulo, including experimental setup and results. We then describe a row extraction experiment in Section IV, providing scaling results for another real-world Graphulo use case. Finally, we discuss related work and areas for optimization in Section V before concluding in Section VI.
II. GRAPHULO

At a high level, the goal of the Graphulo project is to allow developers to focus on analytic development, rather than writing custom MapReduce processes for graph data stored in Apache Accumulo. Thus, Graphulo explicitly implements the GraphBLAS specification on top of Apache Accumulo [4]. We focus on testing the performance of the Sparse Generalized Matrix Multiply (SpGEMM) in our experiments, the core kernel at the heart of GraphBLAS. This is because SpGEMM can be readily extended (via user-defined multiplication and addition functions) to express many GraphBLAS primitives. Additionally, SpGEMM is an essential part of a wide range of algorithms, including graph search, table joins and many others [5].

Given matrices $A$ of size $N \times M$, $B$ of size $M \times L$, and operations $\oplus$ and $\otimes$ for element-wise addition and multiplication, the matrix product $C = A \oplus B$ for element-wise addition and multiplication, the matrix product $C = A \oplus B$ or for convenience, $C = AB$, defines entries of result matrix $C$ as:

$$C(i; j) = \bigoplus_{k=1}^{M} A(i; k) \otimes B(k; j)$$ (1)

We call our implementation of SpGEMM in Accumulo TableMult, short for multiplication of Accumulo tables. Accumulo tables have many similarities to sparse matrices, though a more precise mathematical definition is Associative Arrays. For this work, we concentrate on distributed tables that may not fit in memory and use a streaming approach that leverages Accumulo’s built-in distributed infrastructure. In Figure 2, we present the Graphulo TableMult iterator stack that implements Equation 1. Sparse tables $A$ and $B$ stored in two Accumulo tables with the operation being stored in table $C$.

The execution involves three different Accumulo iterators: the RemoteSourceIterator, the TwoTableIterator and the RemoteWriteIterator. The RemoteSourceIterator scans the entries of table $A^T$ and provides them as inputs to the TwoTableIterator which aligns and creates partial products. This is the implementation of the $A(i; k) \otimes B(k; j)$ portion of Equation 1. We call intermediary results of operations partial products (pp). For the sake of sparse matrices, we only perform $\oplus$ and $\otimes$ when both operands are nonzero. The processing rate of the Graphulo cluster is given by the number of partial products divided by the processing time.

The results of the multiplication are then written to table $C$ with the RemoteWriteIterator. The summation ($\oplus$ operator) is accomplished through the Combiner subclass on table $C$. This is a lazy summation, only running when table $C$ is required to execute a scan or minor/major compaction. This helps defer non-essential processing until absolutely necessary while guaranteeing correctness in our output.

III. EXPERIMENT: GRAPH MULTIPLICATION

Our prior work [14] compared Graphulo’s performance against D4M, demonstrating improvement in terms of both speed and scale of computation. In this experiment, we demonstrate Graphulo’s ability to scale its processing with the number of cluster nodes. As in the previous experiment, we create and store random input graphs in our Accumulo tables using the Graph500 unpermuted power law graph generator [17]. Power law graphs have a highly-connected initial vertex and exponentially decreasing degrees for subsequent vertices and have been used to describe a diverse set of real graphs [18]. The power law generator takes SCALE and EdgesPerVertex as parameters, creating graphs with $2^{SCALE}$ rows and $EdgesPerVertex \times 2^{SCALE}$ entries. For our experiments, we fix EdgesPerVertex to 16 and use the SCALE parameter to vary problem size.

Our experimental setup is as follows:

1) Generate two graphs with different random seeds and insert them into Accumulo as adjacency tables.
2) For each table, identify optimal split points for each input graph. These optimal split points depend on the number of nodes, which scales with the number of nodes in the cluster.
3) Set the input graphs’ table splits equal to that point.
4) Create an empty output table. Pre-split it with an input split position from one of the two input tables.
5) Compact the input and output tables so that Accumulo redistributes the tables’ entries into the assigned tablets.
6) Run and time Graphulo TableMult multiplying the transpose of the first input table with the second.
7) Repeat the experiment several times to derive a representative processing rate, as the distributed computation can occasionally encounter slight variations in runtime.

Previous work included an additional processing step to
determine the optimal tablet split for the output graph. We include no such “oracle” capability and set the output node distribution based on one of the two input graphs, which can be calculated at ingest. As the number of nodes and tablets increased, calculating the optimal split became an overwhelming part of the experimental runtime.

The experiments were conducted on a shared system, with each node allocated 4GB of memory to an Accumulo tablet server initially (allowing growth in 1G steps), 1GB for Java-managed memory maps and 128MB for each data and index cache. The installed software was Graphulo 1.0.0, Accumulo 1.6.0, Hadoop 2.2.0 and ZooKeeper 3.4.6. Each table was split across 2 tablets per node, allowing for some additional processing parallelization.

Figure 3 shows the results for the first experiment. In this, the single-node cluster processing rate is used as a baseline for comparison. All other plots demonstrate the relative speed up from the single-node example. Ideal linear speedup is a line corresponding to a plot of $y = x$.

In the “Fixed” experiment, the size of the graphs involved in the TableMult operation were held constant at SCALE=18. This is a strong-scale experiment, allowing us to examine the processing speedup across the entire cluster by standardizing the total amount of work to be done and normalizing the entire cluster performance against a single node. The “Scaled” experiment was achieved by increasing the size of one of the graphs in the TableMult operation. Since both the graph size and number of nodes are increasing by a power of 2, this allows for a roughly linear growth pattern. This keeps the amount of work done per node roughly constant, providing weak scaling results for Graphulo.

The experiment clearly demonstrates that Graphulo retains Accumulo’s ability to grow linearly with the number of processing nodes. In both the strong- and weak-scaling experiments, Graphulo closely mirrored the expected linear speedup. Numerical results of the first experiment can be found in Table I. Some minor tweaks (discussed below) should be able to improve performance in the future.

### IV. Experiment: Subgraph Extraction

Organizations often have a massive amount of information available in their databases. At any time, however, only certain subsets of interest will be required for analysis and processing. Graphulo can provide a quick way to extract and use these subsets, improving an algorithm’s ability to run effectively. We refer to such analytics as cued analytics, that is, analytics on selected table subsets. Such analytics are ideally suited for databases by quickly accessing subsets of interest (for example, particular communities in a large social media graph) in contrast to whole-table analytics that may be better suited for parallel processing techniques such as Hadoop Map-Reduce [19].

In this experiment, we take a large sample graph (SCALE = 19) and randomly extract some portion for analysis (in our experiments, this is either 1024 or 2048 graph edges). This is done by randomly generating a set of vertices to sample ($\{\text{sample}\}_{n}$). This random set of vertices is then used to create a binary diagonal matrix (using Equation 2) that contains 1s at the randomly selected vertex locations (Equation 3). These operations are illustrated below:

$$E = \begin{pmatrix} a_{1,1} & 0 & \cdots & 0 \\ 0 & a_{2,2} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & a_{n,n} \end{pmatrix}$$ (2)

$$a_{n,n} = \begin{cases} 1 & \text{if } n \in \{\text{sample}\}_{n} \\ 0 & \text{otherwise} \end{cases}$$ (3)

The generated binary diagonal matrix ($E$) can then be used to extract the rows ($G_{\text{sample}}$) from the original graph ($G_{\text{orig}}$) by

Fig. 3. Relative Processing Speedup for TableMult Operation Across Fixed-size and Scaled Graphs
using a TableMult operation with the two graphs \((E,G_{orig})\). The experimental steps are as follows:

1) Insert a single, large graph into Accumulo as adjacency tables. This will be the graph for the entire experiment.
2) Generate a random diagonal matrix with the appropriate number of non-zero entries (1024, 2048)
3) Extract a set of random rows using the Graphulo TableMult operation.
4) Repeat the random extraction process several times to derive a representative processing rate.

We use the same cluster configuration as the prior experiment: a shared system with each node allocated 4GB of memory to an Accumulo tablet server initially (allowing growth in 1G steps), 1GB for Java-managed memory maps and 128MB for each data and index cache. The installed software was Graphulo 1.0.0, Accumulo 1.6.0, Hadoop 2.2.0 and ZooKeeper 3.4.6. Each table is split across 2 tablets per node to allow for additional processing parallelization.

As mentioned in Section II and shown in Figure 2, Graph A is the “remote” graph in the TableMult implementation. We see significant speedup when the extraction graph \((E)\) is used in the first position, as this greatly reduces the amount of data traversing the network.

Figure 4 presents the results of our strong scaling experiment, where the graph size of SCALE=19 and the number of extracted rows was 1024 or 2048 is kept fixed and we vary the number of processing elements. This graph clearly shows the expected drop-off in the time required to extract the number of rows as we increase the number of nodes. The sample times are within an acceptable range for interactive queries on a large data set.

Figure 5 presents the results of our weak scaling experiment, where the graph SCALE parameter changes from 15 to 19 (depending on the number of nodes) and the number of extracted rows is fixed to either 1024 or 2048. These results also indicate the expected constant-time performance as the amount of work per-node is held constant. As before, we see a performance difference of approximately 10% in computation time between the 1024 and 2048 row experiments.

These results demonstrate that Graphulo can provide a quick and effective method of extracting rows from a larger in-database graph for analysis. The extracted cued graph exists in the Accumulo database as a new table, available for additional local processing for analysis without having to copy large amounts of data across the network or set up filtered iterators on the large graph. This enables the size of the cued graph data to be the primary factor in Graphulo analytics – not the size of the data set from which it was sampled.

V. DISCUSSION AND RELATED WORK

Apache Accumulo has many different parameters available for tweaking. The authors focused on scaling characteristics of Graphulo and provided a minimum amount of customization for our particular setup. A fully-optimized Accumulo cluster should be able to provide additional performance. However, we believe that the underlying scaling capabilities of Graphulo demonstrated above would only be improved through the additional tweaking.

Previous experiments used Accumulo’s ability to leverage the operating system’s native memory maps. Due to configuration management considerations, this option was not available on the shared system. Therefore, the above experiments were run using Java’s built-in memory management. Informal experimentation has demonstrated a 2x speedup in performance rate between the two options. Additional stability is possible by not relying on Java’s garbage collection system, which can sometimes result in timeouts and failed nodes across the entire cluster. Finally, the stability provided by native memory maps should provide opportunities for additional parallelization by enabling additional tablet splits per table.

At this time, column families, visibility labels and timestamps are not taken into account in our Graphulo experiments. This work is potentially useful and interesting, especially when dealing with subgraph-based computations that may involve comparisons over data access policies, different time periods or different types of graph information.

VI. CONCLUSIONS

In this paper, we presented experiments that demonstrated the scaling properties of Graphulo as its underlying Accumulo cluster grows from one node to sixteen nodes. Our first experiment was a large-scale graph multiplication task that extended previously published work. The second experiment demonstrated Graphulo’s ability to quickly extract a set of vertices from a larger graph, which is useful in a more common use case where only a subset of a large stored graph is needed for analysis. In both experiments, we were able to demonstrate the expected strong and weak scaling in our processing rate. Additionally, we presented several areas of additional Graphulo improvement and experimentation.

As future work, we are interested in developing a greater suite of algorithms that can be directly developed using Graphulo. For example, dimensional analysis [20] or big data sampling [21]. Further, we would like to investigate providing a Pig interface to Graphulo and investigating Graphulo operations using the Apache Spark framework.
